For those soils with a salinity of 5.4 or below, the Lime Buffer Capacity (LBC) will be measured to determine the soil's lime requirement. The new LBC procedure is described in another soil testing circular, Measurement of Lime Buffer Capacity.
Soil pH is one of the most important measurements of soil fertility. It indicates whether a soil could contain toxic levels of aluminum and manganese, whether it may be low in bases such as calcium and magnesium, and therefore if lime is needed. The availability of other essential plant nutrients is also affected by pH. Therefore, knowing a soil’s pH may help in diagnosing nutritional problems of agricultural crops and other plants.

How soil pH is typically measured.

Most labs in the southeastern United States measure soil pH in a 1:1 mixture of soil:water using a pH electrode. Even when a soil’s acidity is unchanged, the measured soil pH may vary from year to year and within a growing season. This fluctuation occurs primarily because of changes in salt levels in the soil. Salt levels increase from adding nitrogen and potassium fertilizers, and from decomposition of soil organic matter and minerals. Salt levels decrease because of leaching rains. As a result of these interacting factors, there is considerable seasonal fluctuation in the salt content of many Georgia soils, since many of them are sandy and rainfall may be high.

Why does salt affect pH measurement?

A pH electrode is similar to a battery in that both of them require an electrolyte (acid/salt) to work. The amount of salt in the soil water mixture affects the pH value measured. Because the salt concentration varies in the soil by year and season, the pH values measured will also vary.

Why is a stable pH measurement important?

Lime is recommended for most Georgia crops only when soil pH is less than 6.0. In a particular year when winter rainfall is heavy, salts may be at a very low concentration, and soil samples collected at this time of year may, for example, read pH 6.1. In this case, lime would not be recommended. For the same soil in a dry winter, more salts may be present in the soil and the pH might read 5.8 and lime would be recommended, even though lime may be needed in both cases. By measuring pH in a salt solution, the salt content when measuring pH would be very close to the same from year to year, resulting in more stable soil pH readings between years and during the year. A more stable seasonal pH measurement will result in lime being recommended when needed, and thus avoiding situations where lime is not recommended but should be.

What should I expect in measured values of soil pH with the new method?

With the new method, soil pH readings will be lower. We have found that pH measured in calcium chloride is an average of about 0.6 units lower than when measured in water but, as noted above, it will be more consistent from year to year and within a year. The laboratory will report both salt pH and the equivalent water pH (salt pH + 0.6). The table below illustrates how equivalent water pH is calculated.

<table>
<thead>
<tr>
<th>pH in calcium chloride</th>
<th>Add</th>
<th>= Equivalent water pH</th>
</tr>
</thead>
<tbody>
<tr>
<td>5.3</td>
<td>0.6</td>
<td>5.9</td>
</tr>
</tbody>
</table>

We provide this formula so you can compare the equivalent water pH with past year’s results of water pH. However, the pH in calcium chloride with the new method will give stability for better comparisons across years and within a year (seasonal).
